

Gravitational Instability of Cold Matter

Edmund Bertschinger and Bhuvnesh Jain

Department of Physics, MIT, Cambridge, MA 02139

ABSTRACT

We solve the nonlinear evolution of pressureless, irrotational density fluctuations in a perturbed Robertson-Walker spacetime using a new Lagrangian method based on the velocity gradient and gravity gradient tensors. Borrowing results from general relativity, we obtain a set of Newtonian ordinary differential equations for these quantities following a given mass element. Using these Lagrangian fluid equations we prove the following collapse theorem: A mass element whose density exceeds the cosmic mean at high redshift collapses to infinite density at least as fast as a uniform spherical perturbation with the same initial density and velocity divergence. Velocity shear invariably speeds collapse — the spherical tophat perturbation, having zero shear, is the slowest configuration to collapse for a given initial density and growth rate. Two corollaries follow: (1) Initial density maxima are not generally the sites where collapse first occurs. The initial velocity shear (or tidal gravity field) also is important in determining the collapse time. (2) Initially underdense regions undergo collapse if the shear is sufficiently large.

If the magnetic part of the Weyl tensor vanishes, the nonlinear evolution is described purely locally by these equations. This condition is exact for highly symmetrical perturbations (e.g., with planar, cylindrical, or spherical symmetry) and may be a good approximation in many other circumstances. Assuming the vanishing of the magnetic part of the Weyl tensor we compute the exact nonlinear gravitational evolution of cold matter. We find that 56% of initially underdense regions collapse in an Einstein-de Sitter universe for a homogeneous and isotropic random field. We also show that, given this assumption, the final stage of collapse is generically two-dimensional, leading to strongly prolate filaments rather than Zel'dovich pancakes. While this result may explain the prevalence of filamentary collapses in some N-body simulations, it is not true in general, suggesting that the magnetic part of the Weyl tensor does not necessarily vanish in the Newtonian limit.

Subject headings: cosmology: theory — large-scale structure of the universe — gravitation

1. Introduction

According to the gravitational instability theory, cosmic structure developed from the amplification of small density fluctuations generated in the early universe. During the linear stage the amplitude is small and the evolution is described simply by the linearized equations of motion (gravitational field equations plus Boltzmann or fluid equations for the matter and radiation components). If pressure gradients are not too large, self-gravitating fluctuations eventually become nonlinear. The difficulty of following the nonlinear evolution analytically has led cosmologists to resort to gravitational N-body simulations for studying the formation of galaxies and large-scale structure (e.g., Bertschinger 1991 and references therein). However, these simulations should be accompanied by analytical models enabling one to check and comprehend the results.

There are two nonlinear models that have been widely used to describe nonlinear gravitational evolution in cosmology. The first is the spherical model, for which a simple exact solution exists (Tolman 1934; Bondi 1947; Partridge & Peebles 1967; Gunn & Gott 1972; Peebles 1980, §19). For pressureless spherical collapse one follows the trajectories of spherical mass shells having fixed enclosed mass. This model is generally applied to the formation of dense objects, the logic being that the first structures to collapse are high density peaks, with a nearly spherical distribution of matter surrounding them (Bardeen et al. 1986).

The second model is the kinematical one of Zel’dovich (1970). The key idea here is to extrapolate the linear evolution of peculiar velocity beyond the linear regime (for a review see Shandarin & Zel’dovich 1989). The Zel’dovich method is also Lagrangian but is not restricted to spherical symmetry. Indeed, for plane-parallel perturbations (but not for two- or three-dimensional ones) it is exact for particles whose trajectories have not intersected others.

The Zel’dovich approximation (as it is known in multi-dimensions) has provided a great deal of insight into the initial nonlinear evolution of density fluctuations. Recently it has inspired a number of developments concerning the evolution of the velocity field for irrotational flows. Nusser et al. (1991) showed how to compute the density from the Eulerian velocity field in the Zel’dovich approximation; their work was extended to second

order in Lagrangian perturbation theory by Gramann (1993). Lagrangian perturbation theory has also been developed and applied by Moutarde et al. (1991) and Bouchet et al. (1992). A broader perturbative framework has been developed by Giavalisco et al. (1993). The Zel’dovich approximation has also been used to estimate the probability distribution of density in the nonlinear regime (Kofman 1991; Padmanabhan & Subramanian 1993; Kofman et al. 1994). Bernardeau (1992) has used a somewhat different statistical summation method to relate the density and velocity divergence in the nonlinear regime.

The limitations of the spherical model and Zel’dovich approximation are well known. The first applies only with spherical symmetry while the second gives inaccurate trajectories beyond linear perturbation theory. Various authors have therefore suggested modifications of the Lagrangian approach to increase its accuracy. Buchert (1992) has investigated the linear and nonlinear limits of the Zel’dovich approximation. He and Barrow & Saich (1993) have also studied the effects of vorticity. Gurbatov, Saichev, & Shandarin (1980) and Kofman, Pogosyan, & Shandarin (1990) have proposed adding viscosity to prevent the intersection of fluid trajectories. Lachièze-Rey (1993a,b) has recently developed elegant matrix methods for extending the Zel’dovich approximation beyond linear order by following the evolution of the deformation tensor, the Jacobian of the transformation from Lagrangian to Eulerian coordinates. Matarrese et al. (1992) have suggested the interesting approximation of freezing the initial fluid streamlines using the linear velocity field, in effect treating the velocity potential as constant. Brainerd, Scherrer, & Villumsen (1993) and Bagla & Padmanabhan (1994) have suggested instead treating the gravitational potential as constant. While these approaches have provided valuable insights about nonlinear evolution, they are all based on approximations to the evolution of the gravitational field.

General relativity can contribute to a solution by providing evolution equations for the gravitational field as opposed to the nonlocal static Poisson equation underlying the Newtonian approach. It has long been known among relativists that the Einstein equations and the Bianchi identities provide both dynamical equations and initial-value constraints for the gravitational field, whether specified by the metric or by the Ricci and Weyl tensors (see Ellis 1971 for an excellent overview). Moreover, the relativistic equations naturally lead to a closed set of equations for the fluid variables and gravitational fields specified by the Weyl tensor. The Weyl tensor may be decomposed into electric and magnetic parts; in the Newtonian limit the electric part represents the gravitational tidal field. The Bianchi identities provide an exact Lagrangian evolution equation for the Weyl tensor and, therefore, for the tidal field in the Newtonian limit. Remarkably, when the magnetic part of the Weyl tensor vanishes the evolution of the tidal field is purely local, allowing it to be integrated together with the density and the velocity gradient tensor independently for each mass element.

The fully relativistic Lagrangian equations of motion have been used to describe the linear evolution of cosmological perturbations (Hawking 1966; Ellis & Bruni 1989; Hwang & Vishniac 1990; Bruni, Dunsby, & Ellis 1992). Their application to nonlinear evolution of cosmological fluctuations was first made by Barnes & Rowlingson (1989). A major step applying these methods to large-scale structure was made by Matarrese, Pantano, & Saez (1993), who showed that exact solutions exist prior to orbit-crossing for spherical and plane-parallel perturbations, and that these solutions are identical to the afore-mentioned spherical model and Zel’dovich solution. They also demonstrated a local mapping between Lagrangian and Eulerian coordinates. The Lagrangian fluid method in general relativity has been developed further by Croudace et al. (1993), who introduced an approximation method based on the Hamilton-Jacobi equation.

The current paper presents the Lagrangian fluid approach in its Newtonian framework and applies it to the general problem of nonlinear gravitational collapse beginning from small perturbations of a Friedmann-Robertson-Walker spacetime. In §2 we present the Lagrangian fluid equations and their solution in second-order perturbation theory. Although these equations have been given by Matarrese et al. (1993), our approach emphasizes the Newtonian interpretation in contrast with their general relativistic one. In §3 we present a collapse theorem giving a lower bound on the collapse time of an overdense perturbation. The full equations are integrated assuming vanishing magnetic part of the Weyl tensor in §4, where we present results for both overdense and underdense initial perturbations. Conclusions are given in §5.

2. Nonlinear Evolution of Density, Velocity Gradients, and Tides

The evolution of a pressureless fluid may be described either by the Euler equations, by geodesic equations for individual mass elements, or by Lagrangian fluid equations. Although our goal is a closed system of Lagrangian fluid equations, we begin with the nonrelativistic Eulerian approach because of its greater familiarity. In a perturbed Robertson-Walker universe with expansion scale factor $a(\tau)$ the Euler equations take the following form (Bertschinger 1992):

$$\frac{\partial \delta}{\partial \tau} + \vec{\nabla} \cdot [(1 + \delta)\vec{v}] = 0 , \quad (1a)$$

$$\frac{\partial \vec{v}}{\partial \tau} + (\vec{v} \cdot \vec{\nabla}) \vec{v} = -\frac{\dot{a}}{a} \vec{v} - \vec{\nabla} \phi , \quad (1b)$$

$$\nabla^2 \phi = 4\pi G a^2 \delta \rho = \frac{3}{2} \Omega_0 H_0^2 a^{-1} \delta . \quad (1c)$$

The mass density is $\rho = \bar{\rho} + \delta\rho = \bar{\rho}(\tau)(1 + \delta)$ and the peculiar velocity is $\vec{v} = d\vec{x}/d\tau$ where τ is conformal time ($d\tau = dt/a$, with dots denoting derivatives with respect to τ) and $\vec{x}$ is the comoving position with corresponding gradient $\vec{\nabla} = \vec{e}^i \nabla_i = \vec{e}^i \partial/\partial x^i$ with orthonormal basis vectors: $\vec{e}_i \cdot \vec{e}_j = \delta_{ij}$. Throughout this paper we assume the background space to be flat on scales of interest. Equations (1) are valid for a nonrelativistic pressureless fluid on scales much smaller than the Hubble distance cH^{-1} . In adopting a Newtonian approach we neglect gravitational waves and gravomagnetism (the gravitational effect of vorticity).

We will rewrite the fluid equations in terms of the Lagrangian time derivative following a fixed fluid element, $d/d\tau = \partial/\partial\tau + \vec{v} \cdot \vec{\nabla}$. Each Lagrangian fluid element has a trajectory $\vec{x}(\vec{q}, \tau)$ where $\vec{q}$ is a Lagrangian coordinate so that $d/d\tau$ is the time derivative at fixed $\vec{q}$ while $\partial/\partial\tau$ is taken at fixed $\vec{x}$. Converting the time derivatives from Eulerian to Lagrangian, equation (1a) becomes

$$\frac{d\delta}{d\tau} + (1 + \delta)\theta = 0, \quad \theta \equiv \vec{\nabla} \cdot \vec{v}. \quad (2)$$

From equation (2) we see that we require an evolution equation for the velocity divergence (or expansion scalar). For this purpose we consider the velocity gradient (or rate-of-strain) tensor. We decompose this tensor into its trace and traceless symmetric and antisymmetric parts in the usual way:

$$\nabla_i v_j = \frac{1}{3}\theta \delta_{ij} + \sigma_{ij} + \omega_{ij}, \quad \sigma_{ij} = \sigma_{ji}, \quad \omega_{ij} = \epsilon_{ijk} \omega^k = -\omega_{ji}, \quad (3)$$

where $2\vec{\omega} = \vec{\nabla} \times \vec{v}$ is the vorticity and ϵ_{ijk} is the three-dimensional Levi-Civita symbol. The unperturbed Hubble flow is absent from θ because $\vec{v}$ is the peculiar velocity. Taking the divergence of equation (1b), using equations (1c) and (3), and converting the time derivative from Eulerian to Lagrangian, one obtains the Raychaudhuri equation:

$$\frac{d\theta}{d\tau} + \frac{\dot{a}}{a}\theta + \frac{1}{3}\theta^2 + \sigma^{ij}\sigma_{ij} - 2\omega^2 = -4\pi G\bar{\rho}a^2\delta, \quad (4)$$

where $\omega^2 \equiv \omega^i \omega_i$.

Next we require evolution equations for the shear σ_{ij} and vorticity. These follow from the traceless symmetric and antisymmetric parts of the gradient of equation (1b). The curl gives

$$\frac{d\omega^i}{d\tau} + \frac{\dot{a}}{a}\omega^i + \frac{2}{3}\theta\omega^i - \sigma^i_j \omega^j = 0. \quad (5)$$

The traceless symmetric part of the gradient of equation (1b) gives

$$\frac{d\sigma_{ij}}{d\tau} + \frac{\dot{a}}{a}\sigma_{ij} + \frac{2}{3}\theta\sigma_{ij} + \sigma_{ik}\sigma^k_j + \omega_i\omega_j - \frac{1}{3}\delta_{ij}(\sigma^{kl}\sigma_{kl} + \omega^2) = -E_{ij}, \quad (6)$$

where $E_{ij} \equiv \nabla_i \nabla_j \phi - (1/3) \delta_{ij} \nabla^2 \phi$ is the gravitational tidal field, known in general relativity as the electric part of the Weyl tensor in the fluid frame (Hawking 1966; Ellis 1971).

Equations (2) and (4)–(6) give a nearly closed system of equations for the mass density and the velocity gradient (represented by the expansion, shear, and vorticity) following a Lagrangian fluid element. However, the gravitational tidal field remains. In the Newtonian framework, E_{ij} is found after solving the Poisson equation for ϕ . Because this is a nonlocal operation involving the mass distribution everywhere, it would appear to be impossible to obtain a set of Lagrangian equations for one mass element.

This conclusion is false. In general relativity, the field equations are equivalent to a set of evolution equations plus constraints. The Poisson equation corresponds to one of the constraints, the ADM energy constraint equation. However, there exist evolution and constraint equations for all of the gravitational fields, including the tidal tensor E_{ij} . It is possible to obtain an evolution equation for E_{ij} . However, this equation is not necessarily local.

Ellis (1971) gives a clear discussion of the Lagrangian evolution equations and constraints for gravitational fields in general relativity. Equations of motion for the Weyl tensor (giving that part of the gravitational field not produced by local sources) follow from the Bianchi identities rather than the Einstein equations. Assuming that the matter has nonrelativistic peculiar velocities and pressure, the evolution equation for the electric part of the Weyl tensor (Ellis 1971; Matarrese et al. 1993; Croudace et al. 1993), expressed in comoving coordinates, is

$$\frac{dE_{ij}}{d\tau} + \frac{\dot{a}}{a} E_{ij} + \theta E_{ij} + \delta_{ij} \sigma^{kl} E_{kl} - 3\sigma^k_{(i} E_{j)k} + \epsilon^{kl}_{(i} E_{j)k} \omega_l - \nabla_k \epsilon^{kl}_{(i} H_{j)l} = -4\pi G \rho a^2 \sigma_{ij} . \quad (7)$$

Parentheses around a pair of subscripts indicates symmetrization: $\sigma^k_{(i} E_{j)k} \equiv \frac{1}{2} (\sigma^k_i E_{jk} + \sigma^k_j E_{ik})$. The fully antisymmetric Levi-Civita tensor is ϵ_{ijk} (with $\epsilon_{123} = +1$ in Cartesian coordinates). The magnetic part of the Weyl tensor is denoted H_{ij} . We have not assumed that density fluctuations or the velocity gradient are small; the total mass density ρ (as opposed to the fluctuation $\delta\rho$) appears on the right-hand side. As in the preceding equations, the time derivative is Lagrangian, so that each fluid element $\vec{q}$ is assigned a value $E_{ij}(\vec{q}, \tau)$.

Aside from the term involving H_{ij} , equation (7) is purely local. Thus, if $H_{ij} = 0$, we have obtained a closed set of local Lagrangian equations for the nonlinear evolution of pressureless irrotational matter. This fact was first noted by Barnes & Rowlingson (1989) and applied in cosmology by Matarrese et al. (1993, 1994). If $H_{ij} = 0$ and if equation (1c) is applied as a constraint at some initial time, then integrating equation (7) for E_{ij} gives

exactly the same results (prior to orbit-crossing) as if E_{ij} were computed from the solution of the Poisson equation at the final time.

Do local evolution equations for the gravitational tidal field violate causality? No, because they follow directly from general relativity, which is manifestly causal. The resolution of this paradox is the fact that on account of the Bianchi identities the Einstein field equations contain information about the evolution of the matter: the contracted Bianchi identities imply local energy-momentum conservation. Causality is preserved as long as the motion of the matter is such as to generate no gravitational radiation.

We shall not write down the evolution equation for H_{ij} here; it is given by Ellis (1971). It is clear that if the gradient of H_{ij} (which appears in eq. [7]) is nonzero, local evolution breaks down and the evolution of the tide and velocity variables becomes much more complicated. In this paper we shall either restrict ourselves to proving results that are valid independently of the value of H_{ij} , or we shall assume that it can be neglected. While the latter choice is not entirely satisfactory, it may be regarded as an approximation whose validity is to be established later. By making this approximation we can easily integrate the evolution equations and compare the results against N-body or other fully numerical solutions. Thus, we can make strong predictions about gravitational collapse that can be used to assess the importance of the magnetic part of the Weyl tensor even if we lack a good Newtonian interpretation.

Equation (5) shows that if $\vec{\omega} = 0$ initially, it remains zero. This statement remains valid for individual collisionless mass elements even after trajectories intersect. In the following we assume that primeval vorticity is negligible so that $\vec{\omega} = 0$.

We will see below that for growing-mode fluctuations in the linear regime with $H_{ij} = 0$, $E_{ij} \propto \sigma_{ij}$ and therefore the eigenvectors of these matrices are aligned. If we choose our coordinate axes to be aligned with these eigenvectors initially, then equations (6) and (7) are diagonal, implying that the eigenvectors remain fixed in direction (Barnes & Rowlingson 1989). Thus, each of the tensor equations (6) and (7) may be reduced to equations of motion for two of the eigenvalues (with the sum of eigenvalues vanishing for a traceless matrix). For convenience we write the tensors in the following form:

$$\sigma_{ij} = \frac{2}{3} \sigma Q_{ij}(\alpha) , \quad E_{ij} = \frac{8\pi}{3} G \bar{\rho} a^2 \epsilon (1 + \delta) Q_{ij}(\beta) , \quad (8)$$

where we have introduced new scalars $\sigma \leq 0$, $\epsilon \geq 0$, α , and β , and a one-parameter traceless quadrupole matrix

$$[Q_{ij}(\alpha)] \equiv \text{diag} \left[\cos \left(\frac{\alpha + 2\pi}{3} \right), \cos \left(\frac{\alpha - 2\pi}{3} \right), \cos \left(\frac{\alpha}{3} \right) \right] . \quad (9)$$

In the following we will refer to σ and ϵ as the shear and tide scalars, respectively. Similarly, α and β are called the shear and tide angles, respectively. These angles give the ratios of eigenvalues (or axis ratios) of the shear and tidal tensors.

This matrix representation is convenient because all possible eigenvalues are obtained by $q Q_{ij}(\alpha)$ with $q \in [0, \infty)$ (or $-q$ in the same range) and $\alpha \in [0, \pi]$. Although $Q_{ij}(\alpha)$ is periodic with period 6π rather than 2π , $Q_{ij}(\alpha \pm 2\pi)$ and $Q_{ij}(-\alpha)$ differ from $Q_{ij}(\alpha)$ only by permutation of the coordinates. The reduction of the angular range by a factor of six corresponds to ordering the eigenvalues so that $Q_{11} \leq Q_{22} \leq Q_{33}$. Two of the eigenvalues are negative for $\alpha \in [0, \pi/2)$ while two are positive for $\alpha \in (\pi/2, \pi]$. The sum of the eigenvalues vanishes. The square and determinant of Q_{ij} are simple: $Q^{ij}Q_{ij} = \frac{3}{2}$, $\det[Q_{ij}(\alpha)] = \frac{1}{4} \cos \alpha$. We will also need the following differential and product identities:

$$dQ_{ij}(\alpha) = \frac{1}{3} Q_{ij} \left(\alpha + \frac{3\pi}{2} \right) d\alpha, \quad 2Q_{ik}(\alpha)Q_{kj}(\beta) = \cos \left(\frac{\alpha - \beta}{3} \right) \delta_{ij} + Q_{ij}(-\alpha - \beta). \quad (10)$$

Substituting equations (8) into equations (6) and (7) and using equations (2), (9), and (10), we get the following equations of motion for the shear and tide scalars and angles:

$$\frac{d\sigma}{d\tau} + \frac{\dot{a}}{a} \sigma + \frac{1}{3} \sigma (2\theta + \sigma \cos \alpha) = -4\pi G \bar{\rho} a^2 \epsilon (1 + \delta) \cos \left(\frac{\alpha - \beta}{3} \right), \quad (11)$$

$$\frac{d\alpha}{d\tau} - \sigma \sin \alpha = 12\pi G \bar{\rho} a^2 \frac{\epsilon (1 + \delta)}{\sigma} \sin \left(\frac{\alpha - \beta}{3} \right), \quad (12)$$

$$\frac{d\epsilon}{d\tau} - \sigma \epsilon \cos \left(\frac{\alpha + 2\beta}{3} \right) = -\sigma \cos \left(\frac{\alpha - \beta}{3} \right), \quad (13)$$

$$\frac{d\beta}{d\tau} + 3\sigma \sin \left(\frac{\alpha + 2\beta}{3} \right) = -\frac{3\sigma}{\epsilon} \sin \left(\frac{\alpha - \beta}{3} \right). \quad (14)$$

Equations (13) and (14) have assumed $H_{ij} = 0$. Equations (11)–(14) have singular solutions with δ , $-\theta$, $-\sigma$, and ϵ diverging for finite τ . When approaching a singularity by numerical integration we change the independent variable from τ to $x \equiv \ln(1 + \delta)$ with $dx = -\theta d\tau$ and then integrate $\tau(x)$ and $(\theta/\delta)(x)$, $(\sigma/\theta)(x)$, and $(\epsilon/\delta)(x)$ in place of $\delta(\tau)$, $\theta(\tau)$, $\sigma(\tau)$, and $\epsilon(\tau)$.

With zero vorticity and pressure, equations (2), (4) (with $\sigma^{ij}\sigma_{ij}$ becoming $\frac{2}{3}\sigma^2$), and (11)–(14) completely determine the evolution of the density, expansion, shear, and tides until fluid trajectories intersect. We assume that at early times the perturbations were small, $\delta^2 \ll 1$, and $\Omega \approx 1$ (this is generally valid even if $\Omega \neq 1$ today). The solution of the linearized equations then gives $\delta = \delta_0 a(\tau)$ and $\theta = -\dot{\delta}$. However, we must also specify

the initial eigenvalues of the shear and tidal tensors. For gravitationally-induced linear perturbations these two tensors are proportional to each other, as one may see by linearizing equation (6). Thus, altogether we need three constants to specify a growing-mode solution. We take these to be the linear density fluctuation δ_0 , tide (or shear) scalar ϵ_0 , and tide (or shear) angle α_0 . These quantities are simply related to the double gradient of the gravitational potential:

$$\nabla_i \nabla_j \phi = \Omega_0 H_0^2 \left[\frac{1}{2} \delta_0 \delta_{ij} + \epsilon_0 Q_{ij}(\alpha_0) \right] , \quad (15)$$

where we have assumed that coordinate axes have been oriented locally to coincide with the eigenvectors of $\nabla_i \nabla_j \phi$.

In terms of the perturbation constants $(\delta_0, \epsilon_0, \alpha_0)$ the second-order solution for small a is

$$\delta = a\delta_0 + \frac{1}{2}a^2(\delta_0^2 + \theta_1) , \quad \theta = -\dot{a}(\delta_0 + a\theta_1) , \quad \theta_1 = \frac{1}{21}(13\delta_0^2 + 8\epsilon_0^2) , \quad (16a)$$

$$\sigma = -\dot{a}(\epsilon_0 + a\sigma_1) , \quad \sigma_1 = \frac{1}{21}(26\epsilon_0\delta_0 - 5\epsilon_0^2 \cos \alpha_0) , \quad \alpha = \alpha_0 + \frac{5}{7}a\epsilon_0 \sin \alpha_0 , \quad (16b)$$

$$\epsilon = a(\epsilon_0 + a\epsilon_1) , \quad \epsilon_1 = \frac{13}{21}(\epsilon_0\delta_0 - \epsilon_0^2 \cos \alpha_0) , \quad \beta = \alpha_0 + \frac{13}{7}a\epsilon_0 \sin \alpha_0 . \quad (16c)$$

In the linear regime the expansion scalar is proportional to minus the density perturbation and the shear tensor is proportional to minus the tidal tensor, implying $\nabla_i v_j \propto -\nabla_i \nabla_j \phi$. This proportionality occurs because for growing-mode perturbations, the peculiar velocity is proportional to the gravity vector $-\vec{\nabla}\phi$. Thus, the initial conditions may be specified by the eigenvalues of either $\nabla_i \nabla_j \phi$ or $-\nabla_i v_j$, as they are equivalent. However, the proportionality of the shear and tide is broken in second-order perturbation theory.

3. Collapse Theorem

We note from equations (2) and (4) that shear (nonzero σ) increases the rate of growth of the convergence $-\theta$, thereby increasing the rate of growth of density fluctuations. Vorticity (nonzero ω) inhibits this process. With zero shear and vorticity the velocity gradient tensor is isotropic (eq. [3]), corresponding to uniform spherical collapse with radial motions toward some center. This suggests that uniform spherical perturbations grow more slowly than others.

To extend this argument into a theorem we combine equations (2) and (4) into a second-order differential equation for $\delta(\tau)$:

$$\ddot{\delta} + \frac{\dot{a}}{a} \dot{\delta} = \frac{4}{3} \frac{\dot{\delta}^2}{1 + \delta} + (1 + \delta) \left(\frac{2}{3} \sigma^2 - 2\omega^2 + 4\pi G \bar{\rho} a^2 \delta \right). \quad (17)$$

This equation is exact for pressureless matter, regardless of whether the magnetic part of the Weyl tensor vanishes. We see that if $\omega = 0$, the growth rate of δ is minimized for $\sigma = 0$. This conclusion holds independently of assumptions about the evolution of the shear or tides and is due to the simple geometrical fact that shear increases the rate of growth of the convergence of fluid streamlines.

When $\sigma = \omega = 0$, equation (17) reduces to the exact equation for the evolution of the mean density in the spherical model. In other words, this equation is equivalent to the equation of motion for a spherical shell of proper radius $r(t)$ enclosing a fixed mass M related to δ by $1 + \delta = 3M/(4\pi\bar{\rho}r^3)$. From the exact solution it is known that spherically symmetric growing density fluctuations collapse if $\delta_i = a_i\delta_0 > (3/5)(\Omega_i^{-1} - 1)$ where δ_i and Ω_i refer to the density fluctuation and cosmic density parameter at initial expansion parameter a_i (Peebles 1980, §19E). If $\Omega = \Omega_i = 1$, the collapse of a spherical overdense perturbation occurs at $a = a(\tau_c) \equiv a_c$ obeying the well-known relation

$$a_c^{-1}(\delta_0 > 0, \epsilon_0 = 0) = \frac{5}{3} \left(\frac{2}{3\pi} \right)^{2/3} \delta_0 = C_1 \delta_0, \quad (18)$$

with $C_1 = 0.592954\dots$. In other words, if linear theory would imply $\delta = 1$ at $a = 1$, then the density of a uniform spherical perturbation becomes infinite at $a = C_1^{-1} = 1.68647\dots$

Based on the above considerations, we are led to state the following *Collapse Theorem* for overdense growing fluctuations: A pressureless, irrotational mass element with initial density fluctuation $\delta_i > (3/5)(\Omega_i^{-1} - 1)$ collapses *at least as fast* as a uniform spherical perturbation with the same initial δ and $\dot{\delta}$, unless it first collides with another mass element. The proof is trivial, following at once from equation (17) combined with the solution of the spherical model.

Collision with another mass element inhibits collapse only if the matter is collisional, in which case a shock wave is formed and the matter is compressed a finite amount. If the matter is collisionless, intersection of mass elements always increases δ so that the collapse of each individual stream is speeded up.

It is worth noting that the collapse theorem really makes two statements. First, any growing-mode perturbation with $\delta_i > (3/5)(\Omega_i^{-1} - 1)$ collapses (or collides with another element) in a finite time. Second, shear speeds up the collapse. These two facts suggest

two corollaries. First, the collapse condition $\delta_i > (3/5)(\Omega_i^{-1} - 1)$ may be too weak in the presence of shear: initially underdense mass elements may collapse. Second, because the nonlinear density growth rate depends on the shear, the initial shear affects the collapse time. Therefore, initial density maxima do not strictly identify the mass elements to collapse first. To determine how shear actually affects the collapse it is necessary to integrate all the evolution equations together, which we do in the next section under the assumption of vanishing H_{ij} .

The collapse theorem applies regardless of the spatial geometry of the initial perturbation; it is based only on the trajectories of infinitesimally nearby particles. The theorem and its proof using the Raychaudhuri and mass conservation equations is similar to proposition 4.4.1 of Hawking & Ellis (1973), which underlies one of Hawking’s singularity theorems. However, in the present case no spacetime singularity occurs (i.e., the spacetime remains geodesically complete) despite the collapse of matter to infinite density because we have assumed that the fluctuations are much smaller than the Hubble distance so that the Newtonian gravitational potential (eq. [1c]), and therefore the metric perturbations, remains small.

4. General Solutions for $H_{ij} = 0$

We have shown that the nonlinear evolution of density perturbations depends on the shear and tides. To describe the evolution fully we must integrate the equations of motion for these quantities in addition to the density and expansion scalar. We shall make the simplifying assumption that the magnetic part of the Weyl tensor, H_{ij} , may be neglected.

4.1. Overdense Perturbations

Nonzero shear causes overdense perturbations to collapse sooner than the bound given by the collapse theorem. To find out how much sooner, we have integrated equations (2), (4), and (11)–(14) numerically for $\Omega = 1$ with initial conditions given by equations (16). The expansion factor at collapse a_c was evaluated as a function of the initial tide parameters (ϵ_0, α_0) for $\delta_0 = 1$. Using equations (16) in the linear regime the results may be scaled to any δ_0 . Note that δ_0 refers to the linear amplitude at $a = 1$; the actual integrations began at $a \ll 1$.

The results are shown in Figure 1. As expected, a_c decreases with increasing initial shear (or tide), verifying the collapse theorem. Noticing that the contours are approximately elliptical, we fit the following relation to our numerical results:

$$a_c^{-1}(\delta_0 > 0, \epsilon_0, \alpha_0) = C_1 \delta_0 + C_2 \epsilon_0 (1 - 0.2 \cos \alpha_0) , \quad C_2 = 1.25(1 - C_1) . \quad (19a)$$

The rms and maximum relative errors for a_c in this fit are 1.5 and 3.6 percent, respectively, over the region shown in Figure 1. The fit fails to reproduce the asymmetry of the contours at large radii. An alternative fit, better for large ϵ_0 , is

$$a_c^{-1}(\delta_0 > 0, \epsilon_0, \alpha_0) = C_1 \delta_0 + \epsilon_0 (C_3 + C_4 s + C_5 s^2 + C_6 s^3) \quad (19b)$$

where $s \equiv (1 - \cos \alpha_0)^{1/3}$ and $C_3 = 0.36950$, $C_4 = -0.04219$, $C_5 = 0.26710$, and $C_6 = -0.07404$. The rms and maximum relative errors are now 1.2 and 4 percent, respectively.

Plane-parallel perturbations, with $\epsilon_0 = \delta_0$ and $\alpha_0 = 0$, represent a special case of collapse with a simple exact solution to our nonlinear equations: $\delta(\tau) = \delta_l/(1 - \delta_l)$, $\theta = \sigma = -\dot{\delta}_l/(1 - \delta_l)$, $\epsilon = \delta_l$, and $\alpha = \beta = 0$, where $\delta_l(\tau)$ is the linear solution for the growing mode. This solution, valid for $\delta_l \leq 1$, is identical to the result obtained by applying the standard Zel’dovich (1970) approximation (Matarrese et al. 1993). Croudace et al. (1993) have shown that the fully relativistic solution of this problem is given by the Szekeres (1975) metric.

Zel’dovich (1970) suggested that, owing to kinematical effects, cold gravitational collapse would generically approach the plane-parallel solution. Surprisingly, we find this conclusion to be invalid for the solutions we have obtained. As $\delta \rightarrow \infty$, the solutions generically approach $\sigma = \theta \rightarrow -\infty$ as in the Zel’dovich solution but with $\alpha + 2\beta = 3\pi$ and ϵ diverging (roughly as δ) rather than remaining finite. Over much of the range of initial parameters we find $\alpha \approx \pi$ at the moment of collapse, corresponding to a velocity gradient tensor with one positive and two negative (and equal) eigenvalues in the proportions $1 : (-2 + \alpha') : (-2 - \alpha')$ where $\alpha' \equiv (\pi - \alpha)/\sqrt{3} \ll 1$. In other words, the final state is two-dimensional collapse into a spindle or filament with expansion along the third axis, the opposite of what Zel’dovich predicted. This type of final configuration is achieved even if the behavior in the linear and weakly nonlinear regime is nearly one-dimensional, as we will see in §4.3 below. The final state is purely one-dimensional only if $\alpha_0 = 0$.

Croudace et al. (1993) noted the instability of the plane-parallel solution and suggested that it was due to the neglect of the magnetic part of the Weyl tensor. This is a possibility we cannot disprove because we have neglected H_{ij} . However, we can determine why filaments form in this limit: the prolate configuration is favored by the nonlinear tide-shear coupling

term in equation (7), which is stabilizing for one-dimensional (pancake-like) configurations with $\alpha \approx \beta \approx 0$ but destabilizing for two-dimensional (filamentary) configurations with $\alpha \approx \beta \approx \pi$. For $\alpha = \beta = 0$, E_{ij} has eigenvalues with signature $(-, -, +)$ and σ_{ij} has $(+, +, -)$ (assuming $\epsilon > 0$ and $\sigma < 0$, the generic signs for collapse). The eigenvalues of their product (after subtracting the trace in eq. [7]) have signature $(+, +, -)$, so that this term, opposite in sign to E_{ij} , retards the growth of tides. If $\alpha = \beta = \pi$, all of the signatures are reversed except for the tide-shear coupling term, which therefore becomes destabilizing. This behavior is seen most clearly in equation (13). It is possible that the magnetic term in equation (7) would, under some circumstances, counter the tide-shear coupling. However, this cannot be decided without further investigation. In any case, the results obtained here warn one not to take the generality of the Zel’dovich pancakes for granted given the neglect of nonlinear effects in the kinematical treatment.

A complete physical explanation will have to await a Newtonian derivation of equation (7), on which this result hangs. However, the result is not surprising when one recalls that the gravitational field remains finite at a planar distribution of mass while it diverges at a linear distribution. While it is true that the divergence is greatest for a point-like (spherical) configuration, this state is never reached unless the shear vanishes. As we have seen, shear accelerates collapse, so that the spherical end state is disfavored. Collapsing mass elements find the next best solution, a prolate spindle.

It is now easy to understand the asymmetry of the contours in Figure 1. Initially prolate configurations (with $\cos \alpha_0 < 0$) collapse sooner than initially oblate configurations because the shear and tides are already oriented in the most unstable configuration.

An important consequence of our result is that initial density maxima do not correspond, in general, to minima of the collapse time. Equations (19) show that the initial tide (or equivalently, shear) is of comparable importance to the initial density in determining the collapse time of a mass element.

4.2. Underdense Perturbations

Given the importance of shear and tides in accelerating the collapse of overdense perturbations, it is natural to inquire whether they can cause the collapse of underdense perturbations. To answer this question we integrated the equations of motion with $\delta_0 = -1$. As Figure 2 shows, we found indeed that sufficiently large initial tide can turn an expanding underdense perturbation into a collapsing overdense one. Because the collapse time can

diverge (for sufficiently small initial tide), we graph $a_c^{-1}(\delta_0 = -1, \epsilon_0, \alpha)$. This quantity vanishes at the innermost contour; configurations with smaller tide never collapse before trajectories intersect. Including the dependence on δ_0 , the numerical results are fit by

$$a_c^{-1}(\delta_0 < 0, \epsilon_0, \alpha_0) = \frac{3}{4} C_1(\epsilon_0 + 2\delta_0) + \left(C_7 - \frac{1}{4}C_1\right)(\epsilon_0 \cos \alpha_0 + 2\delta_0) + C_7 \left[(\epsilon_0 \cos \alpha_0 + 2\delta_0)^2 + 3\epsilon_0^2 \sin^2 \alpha_0\right]^{1/2}, \quad (20)$$

with $C_7 \approx 0.0676$. The rms and maximum absolute errors in this fit for a_c^{-1} are 0.021 and 0.046 over the range shown in Figure 2. The fit reproduces the kink at $\epsilon_0 = -2\delta_0$ and $\alpha_0 = 0$, but the location of the $a_c^{-1} = 0$ contour does not match the numerical results exactly. Note that a negative a_c^{-1} implies that collapse does not occur.

By comparing Figures 1 and 2 one may notice that for large ϵ_0 the contours of constant a_c are very similar for $\delta_0 < 0$ and $\delta_0 > 0$. In fact, excluding the kink region mentioned above, equation (19b), provides an excellent fit to both cases! Not only can negative density perturbations collapse in an Einstein-de Sitter universe, with large initial tide ($\epsilon_0 \gg |\delta_0|$) they collapse at nearly the same rate as positive density perturbations.

If the initial tide is small enough then a perturbation does not collapse before it intersects another mass element. In this case the mass drains out of the initial perturbation because its expansion rate always exceeds the Hubble expansion rate ($\theta > 0$). At late times these solutions approach the expanding spherical void solution (Bertschinger 1985) with $1 + \delta \propto \tau^{-3}$, $\theta = \frac{3}{2} \dot{a}/a$, $\sigma \propto -\tau^{-4} \ln \tau$, and $\epsilon = \text{constant}$. The velocity field becomes radial ($\sigma/\theta \rightarrow 0$) despite the nonspherical gravitational potential (ϵ/δ remains finite) because the net gravitational deceleration (proportional to $1 + \delta$) is so small that the perturbation becomes freely expanding, retaining thereafter whatever shape it had prior to entering the homologous expansion phase.

4.3. General Perturbations

It is worthwhile to unify the initial density and tide to obtain a representation of the solutions that is valid for any initial condition. We define a net perturbation Δ and an angle γ so that the linear density perturbation and tide are

$$\delta_0 = \Delta_0 \cos \gamma_0, \quad \epsilon_0 = \frac{\Delta_0}{\sqrt{5}} \sin \gamma_0. \quad (21)$$

The variables $(\Delta_0, \gamma_0, \alpha_0)$ are entirely equivalent to the eigenvalues of $\nabla_i \nabla_j \phi$ (eq. [15]). The ranges of the new variables are $\Delta_0 \in [0, \infty)$ and $\gamma_0 \in [0, \pi]$. The square root factor is introduced to diagonalize the covariance matrix of the variables $(\Delta_0, \gamma_0, \alpha_0)$ for a homogeneous and isotropic random process.

If the linear density field $\delta_0(\vec{x})$ is a gaussian random field, applying the results of Doroshkevich (1970) we find the joint probability distribution

$$dP(\Delta_0, \gamma_0, \alpha_0) = \exp\left(-\frac{\Delta_0^2}{2\sigma_\delta^2}\right) \frac{\Delta_0^5 \sin^4 \gamma_0 \sin \alpha_0}{6\pi \sigma_\delta^6} d\Delta_0 d\gamma_0 d\alpha_0, \quad (22)$$

where σ_δ is the standard deviation of δ_0 . Equation (22) is reminiscent of a three-dimensional gaussian distribution in spherical coordinates aside from three extra powers of $\Delta_0 \sin \gamma_0$. These factors arise because the gravity gradient tensor is specified by three distinct diagonal entries of E_{ij} (and angles giving the orientation of the eigenvectors which have been integrated out) in addition to δ . As a result, the distribution of Δ_0 is shifted to larger values compared with a gaussian, while $\cos \gamma_0$ is much more likely to be small than is $\cos \alpha_0$, which is uniformly distributed in $[-1, 1]$. We therefore change variables from γ_0 to

$$\eta_0 \equiv 1 - \frac{16}{3\pi} \int_0^{\gamma_0} \sin^4 \gamma d\gamma = 1 - \frac{2}{\pi} \gamma_0 + \frac{4}{3\pi} \sin 2\gamma_0 - \frac{1}{6\pi} \sin 4\gamma_0. \quad (23)$$

This variable is uniformly distributed (the measure dP depends on η_0 only through $d\eta_0$) for a homogeneous and isotropic random process, ranging from $\eta_0 = -1$ ($\gamma_0 = \pi$) for tide-free negative density perturbations to $\eta_0 = +1$ ($\gamma_0 = 0$) for tide-free positive density perturbations. The distribution of the remaining variable, Δ_0 , is a simple combination of gamma distributions of the argument of the exponential in equation (22).

Figure 3 shows the inverse collapse factor $(C_1 \Delta_0 a_c)^{-1}$ as a function of the two variables $\cos \alpha_0$ and η_0 , assuming irrotational growing-mode perturbations in an Einstein-de Sitter universe. Because these variables are independently uniformly distributed, this diagram may be viewed as an equal-area representation of the general case; all points in the plane are equally likely for homogeneous and isotropic random initial conditions. Using this interpretation and computing the fraction of the area below the $a_c^{-1} = 0$ contour, we conclude that a randomly chosen mass element has a probability of 0.780 to collapse, implying that 56% of the underdense perturbations (and 100% of the overdense ones) will collapse. While the exact numerical values depend on the assumption that $H_{ij} = 0$, the conclusion that some underdense regions must collapse is valid in general because of the effects of shear. Note that orbit-crossing only hastens collapse since it increases the density and therefore the gravitational focussing of trajectories.

The figure presents our results in a rather different way than Figures 1 and 2. One's first impression may be that for a given Δ_0 the fastest collapse occurs for the most spherical

initial perturbations. However, there are two flaws in this conclusion. First, although increasing η_0 means increasing *ratio* of density to tide, this does not contradict our earlier conclusion that for fixed δ_0 , the slowest collapse occurs for spherical perturbations, because constant δ_0 and decreasing tide is not the same as constant Δ_0 and increasing ratio of tide to density. One must be careful to specify what quantities are being held constant. The second problem is that we find a narrow region of large η_0 where the $(\Delta_0 a_c)^{-1}$ exceeds the spherical collapse value C_1 ; Figure 3 shows the contour $(C_1 \Delta_0 a_c)^{-1} = 1.05$. The contours double back at the top of this region so that $(C_1 \Delta_0 a_c)^{-1} = 1$ on the line $\eta_0 = 1$.

Although the collapse time appears to be a relatively simple function of $\cos \alpha_0$ and η_0 , we do not have yet an accurate fitting formula. Before investing much effort in this venture we should relax the assumption $H_{ij} = 0$, a task we leave for future work.

If we crudely approximate $(C_1 \Delta_0 a_c)^{-1} \approx \frac{2}{3} \eta_0 + \frac{2}{5}$, then local minima of the collapse time correspond to local maxima of $\Delta_0(\frac{2}{3} \eta_0 + \frac{2}{5})$. It would be interesting to see in a realization of a gaussian random field how this quantity differs from δ_0 , whose maxima are widely (and erroneously) considered to be the first points to collapse.

Figure 4 shows the final shape of the collapsed object, as represented by $\cos \alpha$, as a function of the initial parameters. Recalling that $\cos \alpha = -1$ for a two-dimensional (prolate) collapse while $\cos \alpha = +1$ for a one-dimensional (oblate) collapse, we see that, aside from regions with initially small shear ($\eta_0 \approx \pm 1$) and oblate shape ($\cos \alpha_0 \approx 1$), most of the parameter space results in collapses that are nearly two-dimensional. In the shaded region the eigenvalues of the velocity gradient tensor deviate by less than 10 percent from the ratios $1 : -2 : -2$ for a filament collapsing along two dimensions. This result confirms and extends what we found in §4.1 above.

5. Conclusions

In this paper we have developed and applied a Lagrangian fluid approach to studying nonlinear gravitational instability. This approach, pioneered by Matarrese et al. (1993), has several advantages over the usual Eulerian description on one hand and the Zel’dovich approximation on the other hand. The first advantage is that we follow the fluid variables associated with a given mass element, which is what we want to do if we are to track the formation of objects by gravitational instability. Second, the Lagrangian fluid flow approach highlights the important physical role played by the shear and tides, quantities that are not so apparent in the Eulerian treatment and are generally neglected in the Zel’dovich approximation.

Going further requires making some assumption about the magnetic part of the Weyl tensor H_{ij} , a quantity having no clear Newtonian interpretation but which may, nevertheless, be present in the Newtonian limit. If it is negligible, as we assumed in §4, then the Lagrangian approach has several additional advantages. The first and clearest is that the pressureless, irrotational flow problem reduces to a small set of six ordinary differential equations for, effectively, the eigenvalues of the velocity and gravity gradient tensors. These equations are easy to integrate to obtain accurate numerical solutions. Second, the method is exact (subject to the above-mentioned assumptions) until orbit-crossing. The Zel’dovich approximation is exact for one-dimensional perturbations. The Lagrangian method is exact for cylindrically and spherically symmetric perturbations also (in these cases H_{ij} vanishes by symmetry). Third, this method is completely local in Lagrangian space (if $H_{ij} = 0$) until trajectories intersect, so that one can follow the evolution of different mass elements independently up to orbit-crossing. The Poisson equation needs to be solved only once at the beginning to give the initial tidal field.

These advantages come with a price: the Lagrangian fluid method does not keep track of particle trajectories. Thus, although one can compute how the density of a given mass element changes with time, one cannot know its position without separately integrating the equations of motion for the trajectory. The Lagrangian fluid equations could be integrated together with the trajectories in order to supplement standard N-body simulation methods. Matarrese et al. (1993) have demonstrated a more elegant method in which only differences in positions are integrated. With standard N-body techniques one can compute the density and shear only by averaging over volumes large enough to contain several particles. With the fluid flow approach the density and other quantities would be evolved for each particle, although the densities would have to be coarse-grained in regions of multi-streaming.

In this paper we have stated and proven a theorem for pressureless, irrotational self-gravitating flows: For a given initial δ and $\dot{\delta}$, a uniform spherical perturbation (i.e., one with zero shear) collapses (i.e., reaches infinite density) more slowly than any other shape. The proof requires no assumptions concerning the evolution of shear or tides or the magnetic part of the Weyl tensor. This theorem applies to the evolution of individual mass elements rather than to the global behavior of an extended mass distribution, for which spherical symmetry may still be preferred as a state of lowest energy. Moreover, if one defines collapse by the requirement that all three axes collapse for an ellipsoidal perturbation, then the spherical tophat collapses most rapidly (White & Silk 1979). However, for many applications one wants to know when density singularities first form, in which case our collapse theorem is applicable.

The collapse theorem contradicts standard lore. One’s intuition suggests that uniform

spherical collapse ought to be most efficient because the gravitational field of a point mass is stronger than that for linear or planar distributions. However, this intuition neglects the very important role played by shear, which always acts to increase the rate of growth of fluid convergence $-\vec{\nabla} \cdot \vec{v}$ following a given fluid element. The effect of shear is not apparent in the Euler equations until one writes the time derivatives following a given fluid element.

Although exact analytical results are not currently available, we have numerically integrated the Lagrangian fluid equations assuming $H_{ij} = 0$ to determine the actual collapse time for perturbations with shear and to investigate the nature of the collapse. We found three interesting things. First, underdense regions can collapse if the initial shear is large enough. One might think this to be unlikely, but we showed that 56% of underdense perturbations (assuming a homogeneous and isotropic random process) will collapse if not prevented by shell-crossing. The exact percentage may differ if we relax the condition $H_{ij} = 0$.

Second, local minima of the collapse time do not correspond to local maxima of the initial density. Instead, they correspond to maxima of a combination of the eigenvalues of the initial gravity gradient (or velocity gradient) tensor. Although we have not obtained an analytical formula for this linear combination, we have given a crude approximation in terms of the variables Δ_0 and η_0 defined in equations (21) and (23).

Third, we showed that when $H_{ij} = 0$, the collapse is generically two-dimensional, in contrast with the prediction of Zel’dovich (1970) that gravitational collapse is one-dimensional. Zel’dovich did not consider the evolution of tides and he gave only a kinematical extrapolation of the linear evolution of trajectories. We find that, even if the initial collapse is nearly one-dimensional, nonlinear coupling between the tide and shear tends to drive the shape of the collapsing mass into a filament rather than a pancake. We gave a heuristic explanation for this, noting that the gravitational field of a filament is stronger than that of a pancake. Although the field of a point mass is still stronger, nonzero shear prevents uniform spherical collapse.

Numerical simulations give conflicting answers to the question of whether cold gravitational collapse is one- or two-dimensional. Loeb & Rasio (1994) find that shear can lead to a filamentary collapse for irrotational perturbations, but White (1993, private communication) found that a uniformly expanding triaxial ellipsoid collapses along one dimension first, in good agreement with the approximate analytic theory of White & Silk (1979) and in disagreement with the results obtained assuming $H_{ij} = 0$. It appears that H_{ij} can cause a pancake-like collapse to occur in some circumstances. Giving H_{ij} a Newtonian interpretation and determining the conditions under which it is significant are important tasks for the future.

Our results have several important implications for the formation of galaxies and large-scale structure by gravitational instability. First, the widely-used spherical tophat collapse model underestimates the rate of gravitational collapse. A good deal of analytic theory in large scale structure has been based on the spherical collapse model, including the Press & Schechter (1974) theory for the mass function of collapsed objects. In a numerical simulation Katz et al. (1993b) noticed that objects with large initial shear collapse sooner as we would predict. Hoffman (1986) first made this point using the Zel’dovich approximation. Second, the two-dimensional character of at least some collapses means that galaxies may be expected to form along filaments. This point was also noted by Katz et al. Moreover, stronger initial tides for a given overdensity imply stronger prolateness of collapsing dark halos, leading to strong influences on the halo shape after virialization (Dubinski 1992). Third, initial density maxima are not the first objects to collapse. Indeed, Katz, Quinn, & Gelb (1993a) found from numerical simulations that many of the first objects to collapse in a cold dark matter model have no initial density maxima associated with them, calling into question the widely-used peak-bias model for galaxy formation. Fourth, matter in underdense regions also collapses unless the initial shear is too low. Thus, it is not clear that one expects galaxy formation to differ much in voids and in moderate-density environments.

In future work we will investigate these implications. We will also test the results using N-body simulations and, conversely, test the N-body method by its ability to reproduce our theoretical results. A final important area of study concerns the evolution of the Weyl tensor. Although we have borrowed results from general relativity, the equations of motion for E_{ij} and H_{ij} should be derivable from Newton’s laws. Conversely, the Newtonian description should help to clarify the proper relativistic treatment after orbits cross as well as the interpretation of H_{ij} .

We wish to thank Andrew Hamilton, Rien van de Weygaert, Simon White, and Fred Rasio for useful discussions. This work was supported by NSF grant AST90-01762.

6. Figure Captions

Fig. 1: Contours of constant collapse time, as indicated by the cosmic expansion factor a_c , versus initial tidal field parameters for linear density perturbation $\delta_0 = +1$. The light (heavy) contours are spaced by 0.1 (0.5), with the central contour $a_c = 1.6$ and the outermost contour $a_c = 0.4$. The maximum collapse time, $a_c = 1.686$, occurs at the center corresponding to zero shear.

Fig. 2: Contours of constant inverse collapse factor a_c^{-1} for initial negative density perturbations with $\delta_0 = -1$. The light (heavy) contours are spaced by 0.1 (0.5), with the innermost contour $a_c^{-1} = 0$ and the outermost one $a_c^{-1} = 1.8$. Initial perturbations in the central region do not collapse, while perturbations with $a_c^{-1} > C_1 = 0.593$ ($a_c < 1.686$) collapse faster than spherical *positive* density perturbations of the same $|\delta_0|$.

Fig. 3: Contours of constant inverse collapse factor a_c^{-1} , normalized to the spherical value C_1 , for perturbations with $\Delta_0 = 1$ (see eq. [21] for the definition). The shape of the initial tidal tensor is specified by $\cos \alpha_0$, with $\cos \alpha_0 = -1$ (+1) for prolate (oblate) perturbations. The parameter η_0 defines the ratio of density to tide, with $\eta_0 = +1$ (−1) for spherical positive (negative) density perturbations and $\eta_0 = 0$ for pure tidal perturbations with $\delta_0 = 0$. The light (heavy) contours are spaced by 0.1 (0.5), aside from the uppermost contour, which is $a_c^{-1} = 1.05 C_1$. The lowest contour is $a_c^{-1} = 0$, below which perturbations do not collapse.

Fig. 4: Contours of constant final shear shape $\cos \alpha$ versus the same initial tidal parameters shown in Figure 3. Starting in the upper right corner and moving to the lower left, the contours are 0 (heavy), −.1, −.2, ..., −.9 (heavy), −.95, −.98, −.99, −.999 (heavy), and thereafter they reverse this sequence. Over most of this plane the final collapse is strongly prolate ($\cos \alpha \approx -1$). The shaded region shows $\cos \alpha < -0.95$.
